

# Auditory attention

- Dichotic listening

Each ear gets a separate channel

Subjects typically can follow one but not the other

- But: Cocktail party effect

Highly salient stimuli can get through the non-attended channel

So where is the filter—early or late?

# Visual attention

- Cueing experiments

Left location

O

Cue location

+

Right location

O

O

O

Cue: “dot will be on the left”

(Variable inter-stimulus interval)

# Visual attention

- Cueing experiments

Subject **never moves their eyes**

Cue is **valid** on 80% of trials, **invalid** on 20%

Dot detection is faster in cued location.

- Attention at the cued location enhances performance
- Conclusion: Attention is like a **spotlight** that moves about the visual field, “enhancing” perception

# Perception without attention

- Some visual features seem to be detected everywhere **in parallel**

Called “**popout**”

Is the red target on the left or the right?

Target

Distractors

Is the slanted target on the left or the right?

/ Target

| Distractors

|

Is the big target on the left or the right?

Target

Distractors

# Perception without attention

- Some visual features seem to be detected everywhere in parallel

Objects with the target feature “pop out” without apparent search

- Visual search paradigm:

Response Time (RT) to detect the target **as a function of the number of distractors**

# Visual search

- Feature search:  
Target has feature X  
Distractors don't  
No effect of #distractors  
→ Parallel search
- Conjunction search

Is the slanted, red target on the left or the right?

/ Target:  $\text{red} \wedge \text{slanted}$

| / Distractors:  $\sim(\text{red} \wedge \text{slanted})$   
 $= \sim\text{red} \vee \sim\text{slanted}$

# Visual search

- Feature search:  
Target has feature X  
Distractors don't  
No effect of #distractors  
→ Parallel search
- Conjunction search  
Target: feature conjunction  
Linear effect of #distractors  
→ Serial search

# Feature binding requires attention

- Primitive feature maps are parallel
- **Combining features** at each location requires attention
- → Complex objects are only perceived within the spotlight of attention!

# Object-based attention

Dot detection is faster at right location than left location

# Object-based attention

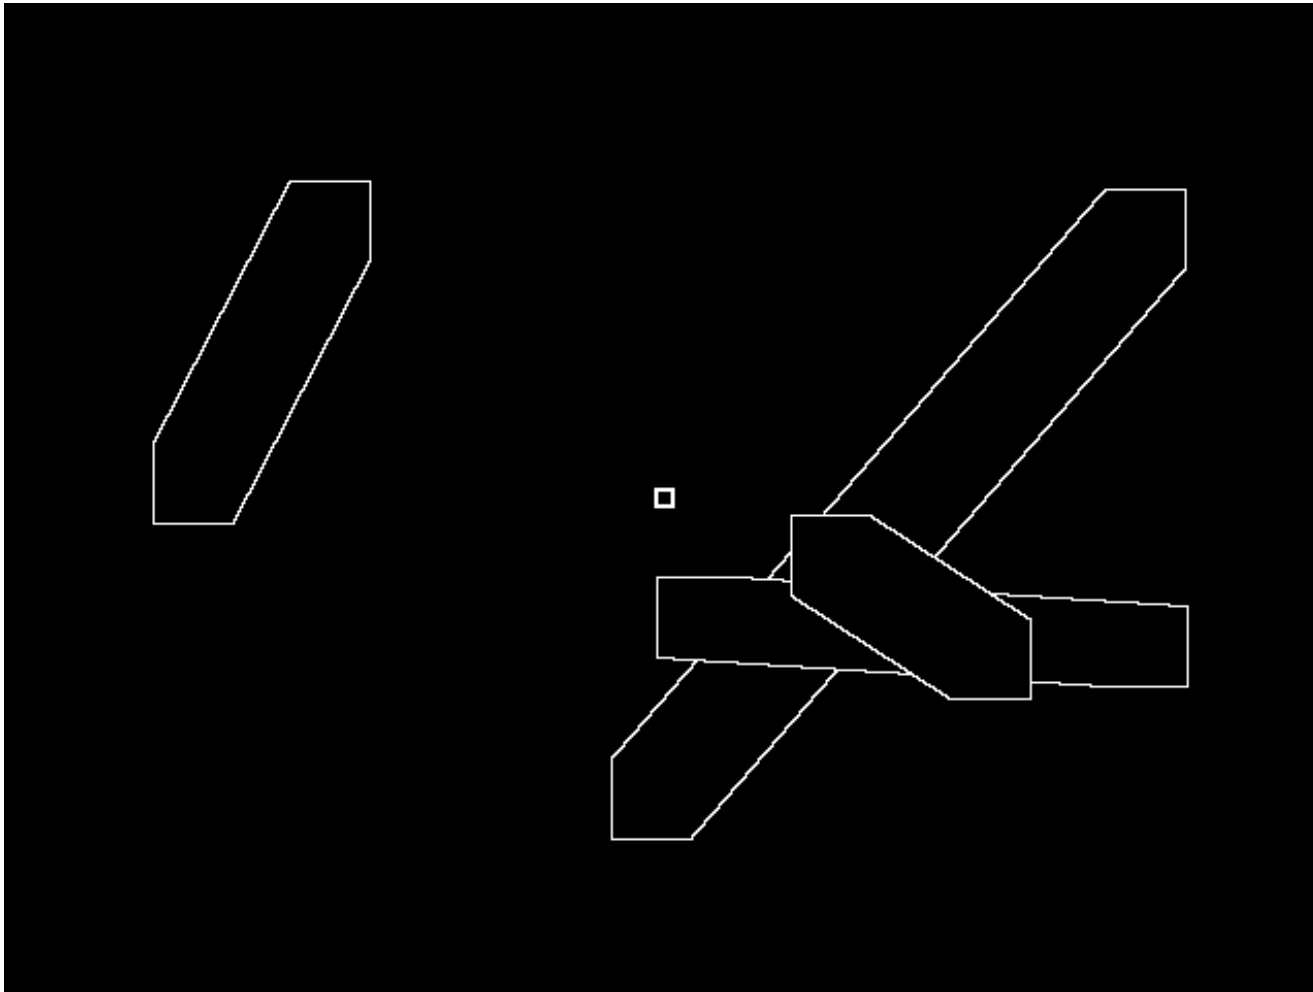

- Attention seems to jump between objects but spread within objects
- Attention seems to select objects, not locations
- Multiple object tracking
  - We can attend about 4 locations (objects) at once
  - But we track distinct objects, not locations.
- Subitizing

# Multiple object tracking

Tracking 4 objects among 8

<http://perception.yale.edu/Brian/demos/MOT-Basics.html>

When targets and distractors are “merged”,  
targets can’t be separately tracked

Even when only a thin line “merges” them, it still makes the task much more difficult
